Received: date / Revised version: date

Abstract. The angular distribution of γ -rays emitted after inelastic scattering of fast neutrons from iron was determined at the *n*ELBE neutron time-of-flight facility. An iron sample of natural isotopic composition was irradiated by a continuous photo-neutron spectrum in the energy range from about 0.1 up to 10 MeV. The de-excitation γ -rays of the four lowest excited states of ⁵⁶Fe and the first excited state of ⁵⁴Fe were detected using a setup of five high-purity germanium (HPGe) detectors and five LaBr₃ scintillation detectors positioned around the sample at 30°, 55°, 90°, 125° and 150° with respect to the incoming neutron beam. The resulting angular distributions were fitted by Legendre polynomials up to 4th order and the angular distribution coefficients a_2 and a_4 were extracted. The angular distribution coefficients of three transitions in ⁵⁶Fe are reported here for the first time. The results are applied to a previous measurement of the inelastic scattering cross section determined using a single HPGe detector positioned at 125°. Using the updated γ -ray angular distribution, the previous cross section results are in good agreement with reference data.

PACS. 25.40.Fq Inelastic neutron scattering – 23.20.En Angular distribution and correlation measurements

1 Introduction

The nuclide ⁵⁶Fe has been included in the recent CIELO international nuclear data evaluation [1] since it is an important structural material in both nuclear engineering and nuclear physics research applications. Due to its relevance for the development and neutronic simulations for innovative fast reactor systems, the inelastic scattering cross section of ⁵⁶Fe is part of the High Priority Request List of OECD/NEA [2].

Recently, a high-resolution measurement of the inelastic scattering cross section was done at JRC-Geel [3]. Neutron differential cross sections were previously measured at University of Kentucky from 1.3 to 7.96 MeV at angles from 30° to 154° and the angle integrated cross section was determined with an energy resolution between 80 to 170 keV [4].

The neutron induced cross sections of ⁵⁶Fe exhibit significant fluctuations that extend from the respective threshold up to energies above 5 MeV. Extending the resolved resonance range in the data evaluation requires high energy-resolution data. Even in the range where the resonances start to strongly overlap the excitation functions still exhibit strong variations if they are measured with sufficiently high resolution. These Ericson fluctuations can be traced back to chaotic scattering in the regime of strongly overlapping resonances and can be explained by random-matrix theory [5]. The compound-nucleus cross sections fluctuate as do the angular distributions of the emitted particles and γ -rays. The fluctuations have the same magnitude as the average cross section. This fact can be used to measure the average width of the compound resonances which for the mass A=60 region might amount to about 10 keV [6].

The recent high-resolution measurement at JRC-Geel was mostly independent of the angular distribution of the γ -rays. The high-purity germanium (HPGe) detectors were positioned under 110° and 150°, where the Legendre polynomial P_4 vanishes. This enables the determination of the angle integrated γ -ray production cross section almost independently of the angular distribution [7].

The angular distribution of 847 keV γ -rays from inelastic neutron scattering from ⁵⁶Fe has been measured before

at the Argonne Fast Neutron Generator [8], where a single Ge(Li) detector was used under different angles. The sample sizes were rather large (cylinders with diam. \times height of 2 cm \times 2 cm and 3.8 cm \times 3.8 cm) and the energy resolution due to the quasi mono-energetic neutron source was about 65 keV. Variations in the γ -ray angular distribution near threshold and decreasing anisotropy with increasing neutron energy was found.

Furthermore there is also a high-resolution measurement of the same angular distribution from ORELA, Oak Ridge, up to a neutron energy of 2100 keV using NE213 liquid scintillators for γ -ray detection under 30°, 90° and 125° [9]. The γ -ray angular distributions from this work however is not included in the EXFOR [10] nuclear data base.

2 Previous cross section measurement

In a previously published work the cross section for inelastic scattering of fast neutrons from excited states in ^{56}Fe was determined using a single HPGe detector [11]. This detector was placed at an angle of $\theta = 125^\circ$ relative to the incoming neutron beam and was used to measure the photon yield $N_{\text{det}}(E_\gamma)$ for the emission of a certain γ -ray energy E_γ . The angle integrated γ -ray production cross section σ_{E_γ} was extracted via the relation:

$$\sigma_{E_\gamma} = \frac{N_{\text{det}} \cdot (1 - p_{\text{mult}})}{\varepsilon_\gamma \cdot f_{\text{trans},\gamma} \cdot W(\theta)} \cdot \frac{1}{\Phi_n \cdot f_{\text{trans},n} \cdot A_{\text{targ}}} \cdot \frac{1}{N_{\text{Fe-56}}} \quad (1)$$

where p_{mult} , $f_{\text{trans},\gamma}$ and $f_{\text{trans},n}$ are correction factors accounting for multiple scattering, γ -ray transmission out of the sample and neutron transmission into the sample, respectively. ε_γ is the γ -ray full energy detection efficiency, Φ_n is the incoming neutron fluence, A_{targ} the geometrical cross section of the sample and $N_{\text{Fe-56}}$ the number of ^{56}Fe nuclei in the sample. See ref. [11] for details. The angular distribution factor $W(\theta)$ was assumed to be unity over the whole neutron energy range, because the Legendre polynomial P_2 vanishes at $\theta = 125^\circ$ and no significant data with sufficient resolution was available for higher order contributions. At the end an average deviation of about 10 % from evaluated and previously measured data was found, that might be caused by this rough assumption. Therefore, a new measurement of the $W(\theta)$ with high neutron energy resolution was performed at the $n\text{ELBE}$ neutron time-of-flight facility and is reported here.

From eq. (1) one can see that the properties of the neutron beam and the sample cancel out when calculating the cross section ratio:

$$\frac{\sigma(\theta)}{\sigma(90^\circ)} = \frac{N_{\text{det}}(\theta) \cdot f_{\text{corr}}(\theta)}{W(\theta)} \cdot \frac{W(90^\circ)}{N_{\text{det}}(90^\circ) \cdot f_{\text{corr}}(90^\circ)} \quad (2)$$

The correction factors $f_{\text{corr}}(\theta)$ combine all corrections, which are different for the individual detectors, *i.e.* efficiency, and γ -ray absorption. The angle-integrated γ -ray

production cross section should be independent of the detector position, *i.e.* $\frac{\sigma(\theta)}{\sigma(90^\circ)} \equiv 1$. Therefore, one can define and determine the normalized angular distribution $W_n(\theta)$ by:

$$W_n(\theta) := \frac{W(\theta)}{W(90^\circ)} = \frac{N_{\text{det}}(\theta) \cdot f_{\text{corr}}(\theta)}{N_{\text{det}}(90^\circ) \cdot f_{\text{corr}}(90^\circ)} \quad (3)$$

The angular distribution $W(\theta)$ can be expressed in Legendre polynomials,

$$W(\theta) = 1 + a_2 P_2(\cos \theta) + a_4 P_4(\cos \theta) + \dots \quad (4)$$

Depending on the multipolarity of the observed γ -rays it is sufficient to use a maximum polynomial order of only 4 to describe the experimental data. From eq. (4) the following expression for W_n can be derived:

$$W_n(\theta) = \frac{1 + a_2 P_2(\cos \theta) + a_4 P_4(\cos \theta)}{1 + \underbrace{a_2 P_2(\cos 90^\circ)}_{=-0.5} + \underbrace{a_4 P_4(\cos 90^\circ)}_{=-0.375}} \quad (5)$$

This function can be used to fit the experimental results to determine the parameters a_2 and a_4 .

3 The $n\text{ELBE}$ neutron time-of-flight facility

The neutron time-of-flight (ToF) facility $n\text{ELBE}$ is the first photo-neutron source at a superconducting electron accelerator. It exhibits a very precise time structure of the neutron pulses and also favorable background conditions due to the low instantaneous neutron flux and the absence of almost any moderating materials. At $n\text{ELBE}$ an electron beam of 30 MeV kinetic energy is focused onto a liquid lead target to produce bremsstrahlung that subsequently produces neutrons via photo-nuclear reactions on the lead nuclei. The short (5 ps) micropulse length and variable continuous-wave repetition rate (typically between 25 and 400 kHz) of the electron beam of the ELBE accelerator [12,13] together with a very compact neutrons-producing target (thickness 11 mm) [14,15] allows using a short flight path (5 to 11 m) and a correspondingly high neutron intensity. With such a neutrons-producing target the energy resolution in the fast neutron range is dominated by the achievable time resolution of the detectors used. The response functions of different neutron ToF facilities are discussed in detail in the review article by Schillebeeckx *et al.* [16].

The $n\text{ELBE}$ neutron spectrum ranges from ca. 10 keV up to 10 MeV. The source strength is typically around $2 \cdot 10^{11}$ n/s which scales down to a neutron flux of approximately $3 \cdot 10^4$ n/cm²/s at the sample position. Further properties of the $n\text{ELBE}$ neutron beam are described in detail in ref. [17]. A schematic view of the $n\text{ELBE}$ facility is shown in fig. 1.

4 Experimental setup

For the present experiment a kinetic energy of 30 MeV, a repetition rate of 101.6 kHz and a bunch charge of 46 pC,

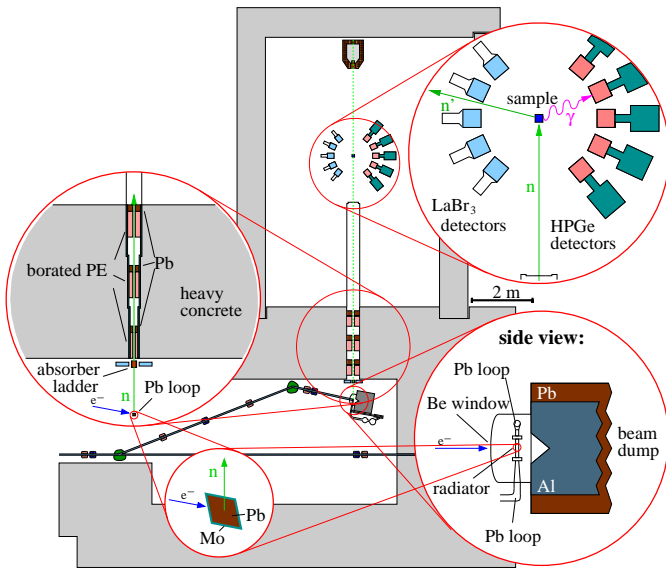

Fig. 1. Schematic floorplan of the n ELBE neutron time of flight facility and the detector setup for angular distribution measurements. The sample is surrounded by five LaBr_3 and five HPGe detectors placed at angles of 30° , 55° , 90° , 125° and 150° with respect to the incoming neutron beam. See text for details.

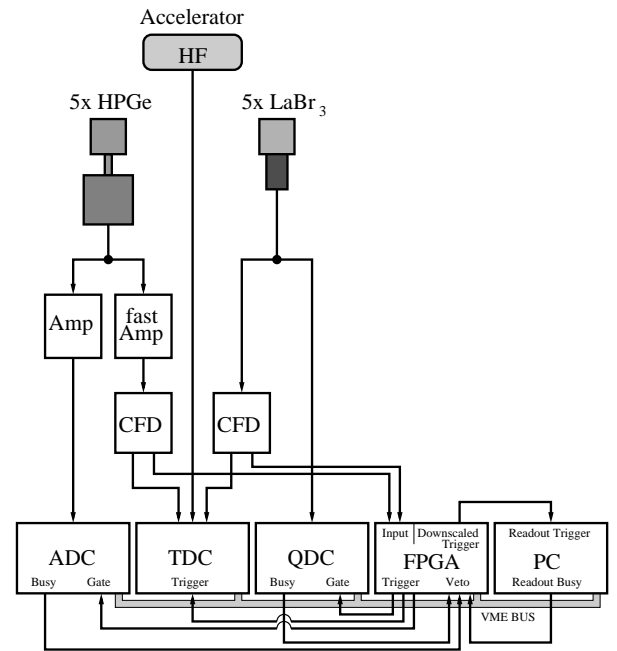

Fig. 2. Schematic view of the data acquisition electronics. See text for details.

i.e. an average beam current of $4.7 \mu\text{A}$, were chosen for the ELBE electron beam parameters.

The sample was a cylindrical disk of natural iron with 4.5 mm thickness, 79 mm diameter and a mass of 172.1 g. It was positioned at a flight path of 830 cm. A tilt of 19.5° between the normal of the sample front face and the beam axis was included to prevent the detectors placed at 90° from pointing perpendicular onto the lateral surface of the sample. Around the sample five LaBr_3 scintillation detectors and five HPGe detectors were arranged in a horizontal plane at distances of 30 cm between sample center point and detector front face. A schematic view of the detector setup is shown in fig. 1.

The LaBr_3 scintillators¹ were cylindrically shaped. One of the scintillators was 2" in diameter and 2" in thickness and was mounted at 30° with respect to the incoming neutron beam. The remaining four scintillators were 3" in diameter and 3" in thickness and mounted at 55° , 90° , 125° and 150° , respectively. Opposite to the beam axis, five cylindrical HPGe detectors² were located at the same angles. Four of the HPGe detectors were about 79 mm in diameter and 89 mm in thickness each (*i.e.* 100 % relative efficiency), the one at 30° was 68 mm in diameter and 77 mm in thickness (*i.e.* 60 % relative efficiency).

The list mode data acquisition system consisted of NIM analog and VME digital electronics, measuring time and energy information for each single detector. An electronics schema is shown in fig. 2. The detector output signals are split into two signal paths: a timing and an energy branch. In the energy branch the signals of the HPGe

detector are amplified and shaped by spectroscopic amplifiers³ and feed into an 8-channel 32-event 12-bit peak-sensing analog-to-digital converter (ADC)⁴. The timing branch consists of a fast amplifier⁵, constant fraction discriminators (CFD)⁶ and a 32-channel multi-event time-to-digital converter (TDC)⁷. This TDC digitizes all incoming signals in a free-running mode into a temporary buffer. When it gets a trigger signal it writes all hits of all detectors inside a pre-defined time interval (match window), even those that occurred before the trigger, into its output buffer. To enable the time-of-flight measurement the high-frequency (HF) reference signal of the accelerator is also fed into the TDC.

The signals emitted by the LaBr_3 detectors are rather short and intense with rise (fall) times of 1 to 2 ns (10 to 20 ns) and amplitudes up to a few volts. Therefore, they don't need further amplification and shaping. For them the energy branch reduces to an 8-channel 32-event charge-to-digital converter (QDC)⁸ and the timing branch to CFDs and the same TDC as for the HPGe detectors.

The CFD signals are also used for trigger production via a field programmable gate array (FPGA)⁹ housed by a multi-purpose logic VME module⁹. This FPGA module creates the logical OR of all detectors to produce the gate signals for the ADC and the QDC and the trigger for the TDC. Furthermore it reads back the busy signals from the

190 ADC and QDC to produce a veto signal to inhibit trigger
 191 production while these modules are converting data.
 192 The length of the veto signal of each trigger event is saved
 193 into a FIFO buffer to enable an event-wise dead time correction.
 194 After 32 events are recorded the FPGA sends a readout trigger
 195 to the VME PC¹⁰ that reads out the data from the buffers of
 196 TDC, ADC and QDC and writes them into list-mode data files
 197 at a network data server.

198 5 Data analysis

199 Figs. 3 and 4 show spectra taken with the experimental
 200 setup and conditions described in the previous section. Ex-
 201 amples of γ -ray energy E_γ versus neutron time-of-flight tof
 202 spectra for one HPGe and one LaBr₃ detector are shown.
 203 The energy and efficiency calibration was done using cali-
 204 brated point sources of ¹³⁷Cs, ⁶⁰Co, ²²⁶Ra and ⁸⁸Y. The
 205 time-of-flight calibration was done using the position of
 206 the photon flash ch_γ (determined by fitting a Gaussian
 207 peak function), the known flight path l (830 cm), the dis-
 208 persion d of the TDC (24.41 ps/channel) and the speed of
 209 light c by means of the following relation:

$$tof = (ch - ch_\gamma) \cdot d + l/c. \quad (6)$$

210 The photon flash is caused by the bremsstrahlung emit-
 211 ted from the neutrons-producing target. In figs. 3 and
 212 4 the photon flash appears as vertical lines at a tof of
 213 about 28 ns and illustrates the different timing properties
 214 of the two detector types. The LaBr₃ detectors show a very
 215 sharp line over the complete γ -ray energy range whereas
 216 the HPGe detectors develop a large tailing especially at
 217 low γ -ray energies. This behaviour is directly correlated
 218 to the shape of the detector's output signals. The signals
 219 caused by scintillation light of the LaBr₃ detectors have
 220 an approximately constant shape, *i.e.* rise and fall time
 221 are independent of the pulse height, whereas the HPGe

detectors develop signals whose rise times vary strongly
 due to the different charge collection times depending on
 the position of γ -ray interaction in the HPGe crystal. Con-
 ventional analog electronics is not capable to correct for
 this behaviour, which results in the limited time resolution
 and the tailing visible in the tof -spectrum.

As the electron bunch length of ELBE amounts to only
 a few ps, the width of the photon flash is given by the time
 resolution of the particular detector. From fitting the pho-
 ton flash with a Gaussian peak function, the time resolu-
 tion results in about 0.8 ns (FWHM) for the LaBr₃ and
 about 10 ns for the HPGe detectors. With an uncertainty
 of about 4.4 cm for the employed flight path (defined by
 half of the thickness of both the neutron source and of the
 detectors) this results in a neutron energy resolution at
 1 MeV, *i.e.* at a tof of 600 ns, of 10 and 35 keV, respec-
 tively.

While the timing properties of the LaBr₃ detectors are
 superior to the ones of the HPGe detector, the latter show
 much better γ -ray energy resolution. For the HPGe detec-
 tors single γ -rays, *e.g.* the ⁴⁰K line at 1461 keV, are visible
 as sharp horizontal lines (cf. fig. 3), while for LaBr₃ these
 lines appear as broad bands. For the γ -ray line at 1173 keV
 from a ⁶⁰Co calibration source, the HPGe detectors show
 a resolution of 3.5 to 4.6 keV (FWHM) and the LaBr₃
 detectors 34 to 41 keV.

Nevertheless, the γ -ray angular distribution can be ex-
 tracted from both detector types. Five γ -ray transitions
 observed in this experiment were analyzed. They are listed
 in table 1. The 1408 keV transition of ⁵⁴Fe could only be
 analyzed in the HPGe detector data due to the closeby
 γ -ray line from the decay of ⁴⁰K at 1461 keV leading to
 overlapping peaks in the LaBr₃ histograms.

The first steps of data analysis were a tof -dependent
 dead time correction according to the description in ref.
 [17] and a background correction via subtraction of spec-
 tra taken with identical experimental conditions but re-
 moved sample. Afterwards the 2D tof - E_γ -histograms with-
 in certain tof intervals, *i.e.* neutron energy intervals, were
 projected onto the E_γ -axis. For the LaBr₃ detectors the

1811	$2^+, 2657.59$	$2^+, 846.78$	M1+E2
1038	$4^+, 3122.97$	$4^+, 2085.10$	M1(+E1)
<u>^{54}Fe:</u>			
1408	$2^+, 1408.19$	$0^+, 0$ (G.S.)	E2

262 *tof* intervals were chosen to have a width of 2 ns for the
 263 most prominent transition at 847 keV and 10 ns for the
 264 others. For the HPGe detectors *tof* intervals of 10 ns were
 265 taken for all transitions. The peaks in the resulting γ -ray
 266 energy histograms were fitted by Gaussian peak functions
 267 plus a linear function to account for the local background
 268 level. The fitted peak area gives the yield $N_{\text{det}}(\theta, E_\gamma, \Delta E_n)$
 269 of γ -rays with energy E_γ produced by neutrons in the en-
 270 ergy interval ΔE_n at an emission angle θ with respect
 271 to the incoming neutron beam. For clarity reasons the
 272 dependency on E_γ and ΔE_n will no longer be explicitly
 273 mentioned in the following discussion.

274 From the yield $N_{\text{det}}(\theta)$ the normalized angular distri-
 275 bution $W_n(\theta)$ can be calculated using eq. (3). Therefore,
 276 the correction factors f_{corr} have to be determined, *i.e.* de-
 277 tection efficiency ε and γ -ray absorption in the sample.

278 The sample is a flat disk of 79 mm diameter and conse-
 279 quently has a different solid angle relative to the γ -
 280 ray detectors than the point-like calibration sources. Simu-
 281 lations using the Monte-Carlo particle transport code
 282 GEANT4¹¹ [20] were performed to determine the efficiency
 283 ratio $\varepsilon_{\text{ext}}/\varepsilon_{\text{point}}$ to take the difference between the cali-
 284 bration measurement and the experiment with a geomet-
 285 rically extended sample into account.

286 It turned out that the extended source efficiency is
 287 not very different from point sources. $\varepsilon_{\text{ext}}/\varepsilon_{\text{point}}$ is in the
 288 range between 0.989 and 1.005 depending on the detector
 289 position and size (cf. table 2).

290 The absorption of neutrons and of γ -rays inside the
 291 sample has also been determined using GEANT4 simu-
 292 lations. Due to the attenuation of the neutron flux, about
 293 5 % less inelastic scattering events happen at the rear side
 294 of the sample compared to the front side. This effect on
 295 the neutron flux cancels out when calculating $W_n(\theta)$ but
 296 slightly influences the mean flight path of γ -rays inside
 297 the sample. Between 11 and 32 % of the 847 keV γ -rays
 298 are absorbed or scattered away on their path from the point
 299 of creation to the detectors depending on the observation an-
 300 gle. This amount decreases for the higher γ -ray energies.
 301 In table 2 examples for the above mentioned correction
 302 factors are listed.

¹¹ GEANT4 was used in version 10.2 patch 2 with G4NDL4.5
 data files and physics list QGSP_BIC_HP 2.0.

**Fig. 5.** Measured (dots) and fitted (lines) γ -ray angular distribution of the $E_\gamma = 847$ keV transition of ^{56}Fe at $E_n \approx 930$ keV (a) and $E_n \approx 980$ keV (b) compared to the data of Smith [8] (blue line).

303 In the end, $W_n(\theta)$ can be determined using the $N_{\text{det}}(\theta)$
 304 and the corrections mentioned above. Fig. 5 shows exam-
 305 ples of the angular distribution of the 847 keV γ -rays from
 306 ^{56}Fe . For these plots two neighboring neutron energy inter-
 307 vals around 930 and 980 keV also used before by Smith
 308 [8] were chosen. The quasi monoenergetic neutron spectra
 309 used by Smith defined an interval width of 65 keV for his
 310 data. The ToF intervals of 2 ns and 10 ns set in the
 311 analysis of the LaBr₃ and HPGe detector data, respec-
 312 tively, correspond to 6 keV and 30 keV wide bins at these
 313 energies. Therefore the neutron-energy resolution of the
 314 HPGe detector data is comparable with that of Smith but
 315 the LaBr₃ results are more detailed. As one can see in fig.
 316 5 the HPGe detector data are consistent with the Smith
 317 data, while the LaBr₃ data reveal strong fluctuations with
 318 energy. This gets even more visible when one determines
 319 the angular distribution coefficients a_2 and a_4 by fitting
 320 the function given by eq. (5) to the measured points. These
 321 fitted curves are shown in fig. 5 as solid lines.

322 6 Results

323 In fig. 6 the resulting angular distribution coefficients of
 324 the 847 keV γ -rays are plotted over the whole energy range
 325 covered by the *n*ELBE neutron spectrum. The comparison
 326 with the data by Smith [8] and also Benjamin *et al.* [21]
 327 shows good agreement with both *n*ELBE data sets. The
 328 HPGe detector data exhibit an energy resolution compa-
 329 rable to the Smith data, while the LaBr₃ data reveal more
 330 details especially in the region below 2 MeV. The a_2 value
 331 is clearly positive and a_4 mainly negative as expected for
 332 a $2^+ \rightarrow 0^+$ E2 transition. Above 2 MeV the angular dis-
 333 tribution flattens out. This is mainly caused by the in-

Table 2. Correction factors for the different detectors. The γ -ray detection efficiency ε_γ , the efficiency ratio between an extended and a point-like calibration source $\varepsilon_{\text{ext}}/\varepsilon_{\text{point}}$ and the γ -ray transmission $f_{\text{trans},\gamma}$ through the sample are tabulated for all detectors for the case of the 847 keV γ -ray from the de-excitation of the first excited state of ^{56}Fe .

**Fig. 6.** Angular distribution coefficients a_2 and a_4 of the 847 keV $2^+ \rightarrow 0^+$ transition of ^{56}Fe . The $n\text{ELBE}$ data are compared to previous measurements by Smith [8] and Benjamin [21].

creasing contribution of feeding transitions from higher states disturbing the spin orientation defined by the incoming neutron. Nevertheless, a positive a_2 value as well as a small negative a_4 component remain up to the end of the energy range investigated.

Figs. 7 to 9 show the angular distribution coefficients for the transition from higher states of ^{56}Fe . For these transition no data could be found in the literature to compare with. Due to lower statistics caused by the lower cross section and the decreasing incoming neutron flux above 2 MeV, these values had to be determined within larger *tof* bins and therefore with poorer energy resolution. Except for the region close to the thresholds, these transitions show rather constant angular distributions over the whole energy range. The 1238 keV transition shows positive a_2

**Fig. 7.** Angular distribution coefficients a_2 and a_4 of the 1238 keV $4^+ \rightarrow 2^+$ transition of ^{56}Fe .

and negative a_4 as it is a stretched E2 transition, while the 1811 keV M1+E2 mixed transition between equal spins is almost isotropic. The uncertainties of a_2 and a_4 for the 1038 keV transition are too large to assign a certain multipolarity but the values are compatible with the known assignment of M1(+E2).

In fig. 10 the angular distribution coefficients for the transition from the first excited state of ^{54}Fe are plotted. The comparison to the few existing data points by Benjamin *et al.* [22] and Guenther *et al.* [23] shows a good agreement. However, the wider energy range covered by the present work reveals much more structure. Qualitatively the angular distribution of the 1408 keV γ -rays of ^{54}Fe is similar to the one of the 847 keV γ -rays of ^{56}Fe , which was expected, because both are $2^+ \rightarrow 0^+$ transitions.

Fig. 8. Angular distribution coefficients a_2 and a_4 of the 1811 keV $2^+ \rightarrow 2^+$ transition of ^{56}Fe .

Fig. 9. Angular distribution coefficients a_2 and a_4 of the 1038 keV $4^+ \rightarrow 4^+$ transition of ^{56}Fe .

7 Application to previous cross section measurement

Using the results for the angular distribution the cross section data determined in the γ -ray production measurement mentioned in sect. 2 and published in ref. [11] can be corrected for angular distribution effects. In that previous work an isotropic γ -ray distribution, *i.e.* $W(\theta) = 1$, was assumed due to a lack of precise data. Now the expression of eq. (4) for $\theta = 125^\circ$ with the coefficients a_2 and a_4 determined in this work can be applied and inserted into eq. (1). In fig. 11 the result of this procedure is compared

Fig. 10. Angular distribution coefficients a_2 and a_4 of the 1408 keV $2^+ \rightarrow 0^+$ transition of ^{54}Fe . The n ELBE data are compared to previous measurements by Benjamin [22] and Guenther [23].

to the data obtained under the assumption of isotropic γ -ray emission. The angular correction causes a reduction of the cross section values by up to 30 %. One can see that the n ELBE data now agree very well with the data of Perey *et al.* [24] and Negret *et al.* [3]. The evaluated data files still show larger deviations of up to 20 % from all the measurements.

8 Summary

The angular distribution of γ -rays emitted during neutron inelastic scattering from a natural iron sample has been determined in the energy range from the reaction threshold up to 10 MeV at the n ELBE neutron time-of-flight facility. Two different sets of detectors, namely five HPGe and five LaBr_3 detectors, have been used to obtain data with different energy and time resolution. The γ -ray yields of five different nuclear transitions of ^{56}Fe and ^{54}Fe (see table 1) have been measured at 30° , 55° , 90° , 125° and 150° relative to the incoming neutron beam. From these yields the normalized angular distribution $W_n(\theta, E_\gamma, E_n)$ has been calculated taking corrections for the data acquisition dead time, the γ -ray detection efficiency, and the neutron and γ -ray absorption in the sample into account. By fitting $W_n(\theta, E_\gamma)$ at a certain neutron energy E_n by the ratio of two Legendre polynomials (see eq. (5)) the angular distribution coefficients a_2 and a_4 have been determined. The angular distribution coefficients for three transitions in ^{56}Fe (1038, 1238 and 1811 keV) are reported here for the first time. The results for the γ -rays from the de-excitation of the first excited states in ^{54}Fe and ^{56}Fe are consistent with previously measured data but contribute knowledge over a much wider energy range. The high neutron-energy

Fig. 11. Inelastic scattering cross section of ^{56}Fe for the excitation of the first excited state ($E_x = 847$ keV). The previously published data [11] were corrected for the γ -ray angular distribution $W(\theta = 125^\circ)$ using the results of the present work. For comparison the data measured by Perey *et al.* [24] and Negret *et al.* [3] and evaluated data from the JEFF [25] and ENDF [26] library are plotted. These reference data were smoothed to the same resolution as the n ELBE data.

407 resolution data taken with the LaBr_3 scintillators reveal
408 a lot of structures that have not been visible before.

409 The results of this work have been used to correct a
410 previously measured inelastic neutron scattering cross section
411 (see ref. [11]) taken at 125° for the effect of the angular
412 distribution. A correction of up to 30 % was calculated,
413 bringing the data in good agreement with previously measured
414 data sets. Since the Legendre polynomial P_2 vanishes at
415 125° this correction is caused only by the $a_4 P_4$
416 term. This fact illustrates the necessity of taking angular
417 distribution effects of higher orders into account. A mea-
418 surement only at 125° might not be enough to determine
419 angle integrated cross sections. As was already stated by
420 others [7], further angles have to be considered, too.

421 We thank the staff of the ELBE accelerator for their valuable
422 support during the experiments and A. Hartmann, K. Heidel
423 and M. Görlner for technical assistance. We also thank St. Gohl
424 and L. Wagner for running shift during the beam time and, last
425 but not least, Nik Kurz from GSI Darmstadt for his assistance
426 during the development of the DAQ.

427 Part of this work was content of the master thesis of Mirco
428 Dietz [27].

429 This work was supported by the European Commission
430 within the 7th framework programme projects ERINDA (FP7-
431 269499) and CHANDA (FP7-605203).
